Abstract—We present Kahuna, an approach that aims to diagnose performance problems in MapReduce systems. Central to Kahuna’s approach is our insight on peer-similarity, that nodes behave alike in the absence of performance problems, and that a node that behaves differently is the likely culprit of a performance problem. We present applications of Kahuna’s insight in techniques and their algorithms to statistically compare black-box (OS-level performance metrics) and white-box (Hadoop log statistics) data across the different nodes of a MapReduce cluster, in order to identify the faulty node(s). We also present empirical evidence of our peer-similarity observations from the 4000-processor Yahoo! M45 Hadoop cluster. In addition, we demonstrate Kahuna’s effectiveness through experimental evaluation of two algorithms for a number of reported performance problems, on four different workloads in a 100-node Hadoop cluster running on Amazon’s EC2 infrastructure.

I. INTRODUCTION

Cloud computing is becoming increasingly common, and has been facilitated by frameworks such as Google’s MapReduce [1], which parallelizes and distributes jobs across large clusters. Hadoop [2], the open-source implementation of MapReduce, has been widely used at large companies such as Yahoo! and Facebook [3] for large-scale data-intensive tasks such as click-log mining and data analysis. Performance problems—faults that cause jobs to take longer to complete, but do not necessarily result in outright crashes—pose a significant concern because slow jobs limit the amount of data that can be processed. Commercial datacenters like Amazon’s Elastic Compute Cloud (EC2) charge $0.10-0.80/hour/node, and slow jobs impose financial costs on users. Determining the root cause of performance problems and mitigating their impact can enable users to be more cost-effective.

Diagnosing performance problems in MapReduce environments presents a different set of challenges than multi-tier web applications. Multi-tier web applications have intuitive time-based service-level objectives (SLOs) as they are required to have low latency. Current state-of-the-art problem-diagnosis techniques in distributed systems rely on knowing which requests have violated their SLOs and then identify the root-causes [4] [5] [6]. However, MapReduce jobs are typically long-running (relative to web-request processing), with Google jobs averaging 395 seconds on 394-node clusters [7], or equivalently, 43 node-hours (i.e., with a 43-node cluster, the average job will run for an hour). These job times are dependent on the input size and the specific MapReduce application. Thus, it is not easy to identify the “normal” running time of a given MapReduce job, making it difficult for us to use time-based SLOs for identifying performance problems.

In the Kahuna technique, we determine if a performance problem exists and identify the culprit nodes, in a MapReduce system, based on the key insight of peer-similarity among nodes in a MapReduce system: (1) the nodes (that we loosely regard as “peers”) in a MapReduce cluster tend to behave symmetrically in the absence of performance problems, and (2) a node that behaves differently from its peer nodes, is likely to be the culprit of a performance problem. In this paper, (1) we evaluate the extent to which the peer-similarity insight is true on Hadoop, the most widely-used open-source MapReduce system, based on empirical evidence from data from real-world research jobs on the 4000-processor, 1.5 PB M45 cluster, a Yahoo! production cluster made available to Carnegie Mellon researchers, and (2) we investigate the extent to which this insight can be used to diagnose performance problems, and contrast these two algorithms based on peer-similarity. We experimentally evaluate two of our earlier problem-diagnosis algorithms based on the peer-similarity insight. These two algorithms diagnose problems in Hadoop clusters by comparing black-box, OS-level performance metrics [8], and white-box metrics derived from Hadoop’s logs [9], respectively, and are examples of algorithms that can be built around the peer-similarity insight. We refer to them as Kahuna-BB and Kahuna-WB respectively. We perform extensive evaluation of these algorithms using multiple workloads and realistically-injected faults.

II. BACKGROUND: MAPREDUCE & HADOOP

Hadoop [2] is an open-source implementation of Google’s MapReduce [7] framework that enables distributed, data-intensive, parallel applications by decomposing a massive job into smaller (map and reduce) tasks and a massive data-set into smaller partitions, such that each task processes a different partition in parallel. Hadoop uses the Hadoop Distributed File System (HDFS) implementation of the Google Filesystem

1We do not claim the converse: we do not claim that a performance problem will necessarily result in an asymmetrically behaving node. In fact, we have observed correlated performance degradations for certain problems, whereby all of the nodes behave identically, albeit incorrectly.
tive fault-coverage with respect to their ability to capture the inputs to Kahuna-BB, shows the inputs to Kahuna-BB, serves data blocks (on its local disk) to HDFS clients. Figure 1 directed by the remote JobTracker, and the DataNode which manages the HDFS regulates access to files by clients (i.e., the Hadoop infrastructure and Hadoop jobs) is the case of heterogeneous cluster configurations; this is outside the scope of the current paper.

Assumptions. We assume that the target MapReduce system (i.e., the Hadoop infrastructure and Hadoop jobs) is the dominant source of activity on every node. We assume that a majority of the Hadoop slave nodes are problem-free and that all nodes are homogeneous in hardware. As a part of future work, we intend to study the peer-similarity principle in the case of heterogeneous cluster configurations; this is outside the scope of the current paper.

Non-goals. We currently aim for coarse-grained problem diagnosis that localizes problems to the culprit slave node(s). This differs from finer-grained root-cause analysis that might aim instead to identify the underlying fault or bug, or offending code. While the presented algorithms can be run online, we focus on the offline evaluation of collected data. We also currently do not target master node problems, nor attempt to predict normal runtimes of a given job.

III. PROBLEM STATEMENT

Our primary research question focuses on whether a peer-similarity based approach can localize performance problems accurately, even in large clusters. Ancillary questions concern the analysis of black-box vs. white-box data, and their respective fault-coverage with respect to their ability to capture the symptoms of various performance problems.

Motivating evidence. To investigate the impact of performance problems on Hadoop, we studied the manifestations of reported bugs from the Hadoop bug database [11] over a 14-month period from Jan 2007 to Feb 2008. We found that 31% of bugs manifested as degraded performance (hangs, performance problems), and a further 35% of bugs manifested as crashes (see Figure 2), indicating that performance problems are an important class of problems to address for diagnosis. Furthermore, we believe that the impact of performance problems is underrepresented in the bug database, as those which do not crash nor halt Hadoop are likely to go unreported.

Goals. Our diagnosis should run transparently to, and not require any modifications of, both the hosted applications and Hadoop itself. Our diagnosis should be usable in production environments, where administrators might not have the luxury of instrumenting applications for code-level debugging, but could likely leverage readily available black-box data or existing native Hadoop logs. Our diagnosis should produce low false-positive rates, in the face of a variety of workloads for the system under diagnosis, even if these workloads fluctuate, as in the case of real-world workloads such as Nutch and Pig. Our data-collection should impose minimal instrumentation overheads on the system under diagnosis.

Fault model. Performance problems in Hadoop clusters can result in jobs taking longer than usual to complete. Such abnormally long runtimes can be due to environmental factors on the node (e.g., an external, non-Hadoop workload), due to causes not specific to the node (e.g., non-deterministically triggered bugs within Hadoop), or due to data-dependent issues. The outcome of our diagnosis algorithm is a set of slave nodes in the cluster that our algorithm has identified as those that caused the job to take longer than usual to complete. We do not attempt to predict the normal completion-time of a given job. Instead, we identify jobs that undergo performance problems that cause the jobs to take longer to complete than if the problem were not present, and identify the nodes that caused the slowdown.

Our data-collection should impose minimal instrumentation in the case of real-world workloads such as Nutch and Pig. Our diagnosis should produce minimal instrumentation overheads on the system under diagnosis, even if these workloads fluctuate, as in the case of heterogeneous cluster configurations; this is outside the scope of the current paper.

Assumptions. We assume that the target MapReduce system (i.e., the Hadoop infrastructure and Hadoop jobs) is the dominant source of activity on every node. We assume that a majority of the Hadoop slave nodes are problem-free and that all nodes are homogeneous in hardware. As a part of future work, we intend to study the peer-similarity principle in the case of heterogeneous cluster configurations; this is outside the scope of the current paper.

Non-goals. We currently aim for coarse-grained problem diagnosis that localizes problems to the culprit slave node(s). This differs from finer-grained root-cause analysis that might aim instead to identify the underlying fault or bug, or offending line of code. While the presented algorithms can be run online, we focus on the offline evaluation of collected data. We also currently do not target master node problems, nor attempt to predict normal runtimes of a given job.

III. PROBLEM STATEMENT

Our primary research question focuses on whether a peer-similarity based approach can localize performance problems accurately, even in large clusters. Ancillary questions concern the analysis of black-box vs. white-box data, and their respective fault-coverage with respect to their ability to capture the symptoms of various performance problems.

Motivating evidence. To investigate the impact of performance problems on Hadoop, we studied the manifestations of reported bugs from the Hadoop bug database [11] over a 14-month period from Jan 2007 to Feb 2008. We found that 31% of bugs manifested as degraded performance (hangs, performance problems), and a further 35% of bugs manifested as crashes (see Figure 2), indicating that performance problems are an important class of problems to address for diagnosis. Furthermore, we believe that the impact of performance problems is underrepresented in the bug database, as those which do not crash nor halt Hadoop are likely to go unreported.

Goals. Our diagnosis should run transparently to, and not require any modifications of, both the hosted applications and Hadoop itself. Our diagnosis should be usable in production environments, where administrators might not have the luxury of instrumenting applications for code-level debugging, but could likely leverage readily available black-box data or existing native Hadoop logs. Our diagnosis should produce low false-positive rates, in the face of a variety of workloads for the system under diagnosis, even if these workloads fluctuate, as in the case of real-world workloads such as Nutch and Pig. Our data-collection should impose minimal instrumentation overheads on the system under diagnosis.

Fault model. Performance problems in Hadoop clusters can result in jobs taking longer than usual to complete. Such abnormally long runtimes can be due to environmental factors on the node (e.g., an external, non-Hadoop workload), due to causes not specific to the node (e.g., non-deterministically triggered bugs within Hadoop), or due to data-dependent issues. The outcome of our diagnosis algorithm is a set of slave nodes in the cluster that our algorithm has identified as those that caused the job to take longer than usual to complete. We do not attempt to predict the normal completion-time of a given job. Instead, we identify jobs that undergo performance problems that cause the jobs to take longer to complete than if the problem were not present, and identify the nodes that caused the slowdown.

Assumptions. We assume that the target MapReduce system (i.e., the Hadoop infrastructure and Hadoop jobs) is the dominant source of activity on every node. We assume that a majority of the Hadoop slave nodes are problem-free and that all nodes are homogeneous in hardware. As a part of future work, we intend to study the peer-similarity principle in the case of heterogeneous cluster configurations; this is outside the scope of the current paper.

Non-goals. We currently aim for coarse-grained problem diagnosis that localizes problems to the culprit slave node(s). This differs from finer-grained root-cause analysis that might aim instead to identify the underlying fault or bug, or offending line of code. While the presented algorithms can be run online, we focus on the offline evaluation of collected data. We also currently do not target master node problems, nor attempt to predict normal runtimes of a given job.
IV. EMPIRICAL EVIDENCE OF PEER-SIMILARITY

Over the past year, we have conducted several experiments with, and analyzed data from, different large-scale MapReduce systems, including our 100-processor Amazon EC2-based Hadoop cluster [12] as well as the 4000-processor Yahoo! M45 production cluster [13]. We experimented with multiple workloads, such as the simple RandWriter and Sort, and the more realistic Nutch and Pig. We have also analyzed traces of Hadoop jobs run by other researchers on M45.

We have observed that, in the absence of performance problems, the slave nodes in a MapReduce cluster tend to exhibit similar behavior, as measured in any number of ways, e.g., CPU usage, network traffic, Map-task completion-times, etc. When we inject a performance problem (or when we observe a problem in the field, in the case of the M45 traces), we observed further that the slave node on which the problem originated (the culprit node) deviated from the other slave nodes in its behavior. These observations held across multiple traces, multiple experiments, multiple users, and testbeds. These two empirically-observed insights—peer similarity under fault-free conditions and peer-divergence indicates a performance problem—form the key motivators of our Kahuna approach, as described in Section V.

Justification. This observed behavior is intuitive and reasonable to expect in a MapReduce cluster. Slave nodes typically process copies of the same task that operate on different inputs; with each task processing large numbers of records, the aggregate behavior of slave nodes that we observe would be similar. In addition, we argue that, for a job to complete as quickly as possible, nodes (with the same processing capabilities) should spend comparable amounts of time handling comparable amounts of work, as the system completes its job only when the slowest node completes. Hence, peer-similarity amongst (homogeneous) nodes is not merely an observed, but also a necessary, characteristic, for optimal performance.

Supporting evidence. We provide empirical evidence from traces of real Hadoop jobs in the Yahoo! M45 production cluster, to support our key insights. We obtained the Hadoop logs for jobs that were run by researchers (whose data-intensive jobs range from machine translation to large-scale data mining) over the five-month period, April–September 2008. The logs spanned 12854 experiments run by 26 users. Each experiment consisted of multiple Hadoop jobs. Table I provides a summary of the log statistics. Apart from the visual inspection of these log traces, we sought to establish, in a statistical way, that (i) slave nodes performing the same jobs behave similarly, and (ii) the similarity between nodes is affected when a job suffers from performance problems.

We measured the similarity among nodes by computing the absolute value of the Pearson’s pair-wise correlation coefficient (between 0 and 1, with 1 expressing maximum similarity) of the average number of Maps/second being executed across slave nodes during a job across every pair of nodes in each job. We considered the number of Maps/second, rather than the number of Reduces/second, because a third of the jobs

V. DIAGNOSIS APPROACH

Based on our key insights in Section IV, we assert that a node whose behavior differs from the majority of nodes in the cluster is anomalous and can be a potential source of a performance problem. To enable us to quantify how similar/dissimilar nodes are to each other, we need to define the notion of “behavior” more concretely. Hence, Kahuna-BB statistically compares black-box data across nodes, and Kahuna-WB statistically compares white-box data across nodes.

Black-box instrumentation. We gather and analyze black-box (i.e., OS-level) performance metrics, without requiring any modifications to Hadoop, its applications or the OS. We use the sadc program in the sysstat package [14] to collect 14 OS metrics, as listed in Table II from /proc, at a sampling interval of one second. We denote each vector containing samples of
these 14 metrics, all collected at the same instant of time, sadc-vector. We use these sadc-vectors as our metric for diagnosis in Kahuna-BB.

White-box instrumentation. We collect the system logs generated by Hadoop’s native logging code from the TaskTracker and DataNode daemons on slave nodes, and use the SALSA log-analysis technique [9] to extract state-machine views of the execution of each daemon. Each entry in the log is treated as an event, and particular events are used to identify states in the control-flow of each daemon, e.g., Map and Reduce states in the TaskTracker, and ReadBlock and WriteBlock states in the DataNode. Sequences of state executions are then generated, with data-flows between these states, and durations of each state, for each node in the cluster. Kahuna-WB compares these durations across slave nodes to perform its diagnosis.

VI. DIAGNOSIS ALGORITHMS

For each of the metrics of diagnosis (sadc-vector for Kahuna-BB and state durations for Kahuna-WB), over a given period of time, we compare that metric’s values at each node with the metric’s corresponding values at all of the other nodes. If the values of metric X at a given node, N, differ significantly from sufficiently many nodes in the cluster, metric X is said to indict node N as the culprit, and our algorithms flag the presence of a performance problem. Kahuna-BB and Kahuna-WB are similar in their use of a peer-comparison strategy, but differ in that (i) they operate on different sets of metrics, (ii) they impose different hypotheses on the data, and (iii) they can operate independently of each other.

A. Kahuna-WB: White-Box Diagnosis

We assume that state durations of interest have been extracted from Hadoop’s logs using [9]. Kahuna-WB performs peer-comparison on the durations of the states extracted through log analysis, i.e., the Map, Reduce, ReduceCopy and ReduceMergeCopy states from TaskTracker logs, and the ReadBlock and WriteBlock states from DataNode logs. For each state, for a given period of time, we generate a histogram of the durations of that state for each node, in order to create an aggregate view of the state’s durations for that node. Then, for each node, we compare its histogram for that state’s duration with the corresponding histograms of every other node in the cluster. We perform this comparison by computing a statistical measure (square-root of the Jensen-Shannon divergence [15]) of the distance between histograms. If a given node’s histogram differs significantly (by more than a threshold value) from those of a majority of the other nodes, then, we diagnose the cluster as undergoing a performance problem with that node being the culprit.

B. Kahuna-BB: Black-Box Diagnosis

Unlike Kahuna-WB, which simply performs a statistical comparison across nodes, Kahuna-BB requires a priori training to summarize system metrics into a small number of behavior profiles. This enables it to extract meaning out of black-box data typically devoid of semantic information. Kahuna-BB is based on two related hypotheses about the behavior of MapReduce slave nodes from the perspective of black-box, OS-level performance counters: (i) that MapReduce slave nodes exhibit a small number of distinct behaviors, and that (ii) in a short interval of time (say, 1s), the system’s performance tends to be dominated by one of these behaviors. We then exploit our peer-similarity insight in Kahuna-BB to incriminate any node whose dominant distinct behavior differs from those of a majority of the other nodes in the cluster.

Learning. The K distinct profiles, each of which captures one of the distinct Hadoop behaviors hypothesized above, are first learned a priori from fault-free runs of various workloads (described in Section VII-A). This phase involves collecting sadc-vectors from these runs, and then using the Expectation-Maximization (EM) algorithm [16] to cluster these sadc-vectors into behavior profiles. These profiles have no semantic meaning, and are used to condense Hadoop’s different behaviors into a small number of profiles, as manifested across all 14 elements of the sadc-vectors.

Diagnosis. First, we classify each node’s sadc-vector into one of the learned K distinct profiles. We then compute the histograms of these profiles for each node, decayed exponentially with time to weight past behavior less. We then compute the pairwise distance between the histograms of every pair of nodes in the cluster in each time period, using a statistical measure (the square-root of the Jensen-Shannon divergence [15]). If a specific node’s histogram differs significantly (by more than a threshold value) from those of a majority of the other nodes, then we declare the system to be undergoing a performance problem and indict that node to be the culprit.

VII. EXPERIMENTAL EVALUATION

Each experiment consists of a {problem, workload} pair, with a Hadoop cluster running a particular workload, with a specific single fault injected at one of the slave nodes during the experiment. These injected performance problems increase the workload’s running time, as compared to the control fault-free case, as shown in Table IV. We evaluate Kahuna-BB’s and Kahuna-WB’s ability to detect and localize the injected performance problems for each Hadoop workload. We selected
these injected problems to cover both (i) resource-contention (CPU, disk, network) problems, as well as (ii) Hadoop bugs that result in performance slowdowns or hangs.

A. Experimental Setup

We collected and analyzed traces from Hadoop clusters running on virtual machines on the Amazon EC2 virtual data-center. Each node consisted of an “extra-large” node instance on EC2, with 4 dual-core Intel Xeon-class CPUs, 15GB of memory, and 1.6TB of Elastic Block Store (EBS) storage [12]. We collected traces from 10-, 25-, 50- and 100-node Hadoop clusters. We collected both black-box, OS-level performance counters throughout the experiment, and white-box Hadoop logs at the end of each experiment for offline processing. Black-box data collection incurred an overhead of less than 1% CPU utilization; white-box data-collection did not require additional effort as Hadoop generates logs by default.

Workloads. To evaluate the effectiveness of Kahuna on a variety of workloads, we collected traces of Hadoop under four different workloads: two simple benchmarks that are packaged with Hadoop (Sort, RandWriter), and two Hadoop applications (Nutch, Pig) commonly used in real-world installations. These are described below:

- **RandWriter**: Write-intensive workload that generated 24 GB of random data on each task
- **Sort**: Read/Write workload that sorts 5 GB of randomly-ordered records generated by RandWriter. Sort and RandWriter are common Hadoop benchmarks
- **Nutch**: Distributed web-crawler for Hadoop, in use at several companies [3], representative of a real-world, fluctuating workload typical of many Hadoop workloads
- **Pig**: High-level language for expressing data analysis programs [17], that is compiled into Hadoop programs, typical of a sophisticated, multi-job Hadoop workload

Fault Injection. Table III describes the faults that we injected into one of the slave nodes in each experiment, and our fault-injection methodology. These faults trigger performance problems reported on the Hadoop users’ mailing list or on the Hadoop bug database [11]. The faults studied were intentionally selected to induce performance problems, specifically those that caused Hadoop jobs to take longer to complete than expected, as compared with our control (i.e. fault-free) experiments. Table IV captures the impact of these injected faults on the job-completion times of the four workloads.

VIII. Results

For each experimental trace, we analyzed the trace-data using both Kahuna-WB and Kahuna-BB, each of which returned a list of nodes it indicted as culprits. We evaluated this outcome as follows: an indictment of the fault.injected node was a true-positive, an indictment of any other node was a false-positive (FP), and a failure to indict the fault.injected node was a false-negative (FN). The true-positive (TP) and false-positive rates $\in [0,1,0)$, with $TP = 1.0, FP = 0.0$ representing a perfect diagnosis) are presented here for 10 fault-induced experimental runs for each {problem, workload} pair. These results are computed for a specific threshold (for Kahuna-BB and Kahuna-WB) for each {workload, cluster-size} pair.

A. Kahuna-BB: Black-box diagnosis

Figures 4, 5, 6, and 7 show the TP and FP rates for each {fault,workload} pair. The bar graphs are grouped by injected fault, and each set of 4 bars shows results for the 10-, 25-, 50-, and 100-node clusters respectively. In general, Kahuna-BB was successful at diagnosing most injected faults on

Fig. 6. Results for all problems on RandWriter for all cluster sizes.

Fig. 7. Results for all problems on Sort for all cluster sizes.

Kahuna-BB performed less than satisfactorily. We candidly discuss deviations where and why Kahuna-BB performed less than satisfactorily.

PacketLoss: The PacketLoss1 problem was generally not diagnosed on all workloads, as compared to other problems, because Hadoop uses TCP, which provides some resilience against minor packet losses. The diagnosis of more severe packet losses had high TP rates, indicating we could detect the problem. However, the high FP rates indicated that we regularly indicted wrong nodes, due to the correlated nature of the problem since a packet loss on one node (e.g. due to a flaky NIC) can also register as a problem on other nodes communicating with it. Also, the PacketLoss problem was less successfully detected on RandWriter because its jobs largely involved disk I/O but minimal network communication.

HANG-2080, HANG-1152: The HANG-2080 and HANG-1152 problems affect the Reduce stage of computation. Since the RandWriter workload has no Reduce tasks, these hang problems have less impact on it (as shown in Table IV) than on Sort and Pig, which have relatively long Reduces. We could not diagnose the problem on the Nutch workload as it affected a majority of the nodes in the cluster, so that peer-comparison failed to diagnose this problem.

DiskFull: The DiskFull problem was not diagnosed successfully on the Pig workload, with relatively low TP rates. In this problem, the node with a full disk would use remote DataNodes rather than its local one to perform operations, so that workloads which perform more disk operations would be more greatly impacted. However, the Pig job in our experiments was largely compute-intensive, and less disk-intensive, so that the drop in disk activity on the problematic node did not cause the disk activity of that node to deviate significantly from those of other nodes.

B. Kahuna-WB: White-box diagnosis

Kahuna-WB diagnosis was performed with the durations of each of the following states: ReadBlock and WriteBlock states on the DataNode, and the Map, Reduce, ReduceCopy and ReduceMergeCopy states on the TaskTracker. We found that diagnosis using the Map state was most effective; we summarize the results for diagnosis using all other states due to space constraints. The Map state was more effective for diagnosis as our candidate workloads spent the majority of their time in the Map state, while only Sort and Pig had significant Reduce tasks, so that the Map state
was more likely to reflect problems. The ReadBlock and WriteBlock states were more likely to reflect problems in read-intensive and write-intensive workloads respectively, but were less effective on workloads with balanced I/O. The ReduceCopy and ReduceMergeCopy states were generally short-lived and occurred sparingly, and so were less effective. We present the FN (= 1 – TP) and FP rates for diagnosis using the Map state in Figures 8 and 9 respectively, and the average FN and FP rates for diagnosis using all other states in Figures 11 and 10 respectively. Each cell in the heatmap shows the FN or FP rate respectively for the given \{ problem, workload \} pair for a given cluster-size (indicated after each workload). Deeper shades and deeper reds show low FN/FP rates, while lighter shades show high FN/FP rates.

**Diagnosis using Maps.** We diagnosed all problems relatively effectively, with low FN rates. However, we suffered high FP rates on the Packet Loss problems due to the correlated nature of packet losses, as explained in Section VIII-A. We also suffered high FP rates on HANG-1152 and HANG-2080 on Nutch and RandWriter, as explained in Section VIII-A.

**Diagnosis using other states** Non-Map states were less effective for diagnosis, achieving poorer (higher) FP and FN rates. In particular, they were ineffective for RandWriter because the workload had no Reduce and minimal ReadBlock states—this small number of non-Map states resulted in higher sensitivity of Kahuna-WB and hence higher FP rates.

**C. Discussion**

Our experimental results show that our peer-comparison approach works well at diagnosing resource faults that result from over- or under-utilization of resources; e.g. in the CPU and DiskHog faults, compute and I/O capacities were excessively used, while in the HANG-1036 fault, compute capacities were underutilized due to the hang. This is reinforced by our diagnosis being more effective on faults that result in more severely increased job runtimes, in comparing Table IV with our diagnostic results. However, the peer-comparison approach works less well on communication failures e.g. packet losses. Also, Kahuna-WB does marginally better than Kahuna-BB at the more subtle faults, i.e. HANG-1152 and HANG-2080 in workloads with significant Reduce activity. Thus, our peer-comparison approach can be applied at different levels of granularity to enable more comprehensive diagnosis coverage.

**IX. RELATED WORK**

We compare our approach with recent work in problem diagnosis in distributed systems in collecting system data and localizing faults to requests or nodes. Also, we target MapReduce environments, which have long-lived jobs relative to the Internet services, with short-lived jobs and easily-defined SLOs, in recent work [18], [4], [9], [6], [20].

**Instrumentation sources.** Magpie [18] uses black-box OS-level metrics, similarly to Kahuna-BB but at a finer granularity with request attribution, which Barham et al. achieve by

**Root-cause analysis.** Given failed requests, [4], [19] perform root-cause analysis on known-failed requests using clustering and decision trees respectively. [5], [20], [6] identify components along request paths, or anomalous paths, that contribute to failures/slowdowns. They uncover root-causes of known failed requests, while Kahuna-WB and Kahuna-BB identify requests with performance problems in systems where knowledge of SLO violations is not easily obtained.

**Peer-comparison techniques.** Peer comparison has been used to identify anomalous nodes or components, in actively replicated systems [23] and load-balanced web-service clusters [24]. Slave nodes in MapReduce and Hadoop clusters are not strictly peers, as they handle different inputs; thus, it is interesting for our hypothesis of peer-symmetry to be borne out. [25] described initial work towards peer comparison in Dryad [26]. PeerPressure [27] diagnoses known configuration faults on a single host offline by comparing the suspect configuration with other labelled ones.

**Diagnosis in MapReduce and Hadoop.** [28] mined error messages in DataNode logs to identify those correlated with actual errors, while we target performance problems. [22] was used to instrument Hadoop to return causal paths for identifying slow paths while we identify slow nodes. [9] presented initial results in comparing state durations in Hadoop’s execution, and [8] compared OS-level metrics; we evaluate these more extensively as part of the peer-similarity hypothesis. [29] presents visualizations of Hadoop behavior as a debugging aid for understanding and optimizing performance.

**X. CONCLUSION**

Kahuna aims to diagnose performance in MapReduce systems based on the hypothesis that nodes exhibit peer-similarity under fault-free conditions, and that some faults result in peer-dissimilarity. This gives rise to our peer-comparison approach, applied to Hadoop, which we have validated using empirical evidence from real-world traces on the Yahoo! M45 cluster, and using experimental evaluation of two earlier peer-comparison algorithms on extensive benchmark and production workloads. Also, the applicability of our peer-comparison approach to multiple levels of Hadoop behavior suggests that this is a generally applicable approach, and our results show that applying peer-comparison to multiple levels (black-box system-level and white-box application-specific) of behavior can enhance the diagnosis coverage.
